Manipulating Strongly Interacting Electrons with Dimensionality and Strain

John W. Freeland
Advanced Photon Source, Argonne National Laboratory

Complex oxides are a class of materials containing a variety of competing strong interactions that create a subtle balance to define the lowest energy state, which leads to a wide variety of interesting properties (e.g. superconductivity, magnetism,...). By utilizing the bulk properties of these materials as a starting point, interfaces between different classes of oxides offer an opportunity to break the symmetry present in the bulk and alter the local environment. Utilizing the advances in oxide growth, one can now combine materials with distinctly different and even competing orders to create new materials in the form of heterostructures. The broken symmetry, strain, and altered environments at the interfaces then provide an avenue to manipulate this subtle balance and perhaps even create new phases. To understand these phases however requires detailed studies of the heterostructure properties. Here I will touch on several recent examples to illustrate how x-ray probes offer the ability to gain unique insight into the underlying physics.
